University

# Functions (*Think Python*, Ch. 3)

---

Australian  
National  
University

- Functions are like mini-programs you can call from your code that do useful, predefined tasks (that you would otherwise you might need to do for yourself)
- We have already seen two:
  - `str(0.1)` converts a number (integer or float) to a string
  - `type(153)` prints the variable type
  - `print('this')` takes a string input and prints it to the terminal
- In python, functions can be:
  - Built-in
  - Imported from modules
  - User-defined

# Built-in Python functions

Australian  
National  
University

- There LOTS of these. A very necessary part of the language
- Go to the source documentation for the Python language (at python.org) and look through what is available:

<https://docs.python.org/3/library/functions.html>

- Each function is described with details of what it does, what input it takes and what output it produces

Built-in Functions			
<b>A</b> <code>abs()</code> <code>aiter()</code> <code>all()</code> <code>any()</code> <code>anext()</code> <code>ascii()</code>	<b>E</b> <code>enumerate()</code> <code>eval()</code> <code>exec()</code>	<b>L</b> <code>len()</code> <code>list()</code> <code>locals()</code>	<b>R</b> <code>range()</code> <code>repr()</code> <code>reversed()</code> <code>round()</code>
<b>B</b> <code>bin()</code> <code>bool()</code> <code>breakpoint()</code> <code>bytearray()</code> <code>bytes()</code>	<b>F</b> <code>filter()</code> <code>float()</code> <code>format()</code> <code>frozenset()</code>	<b>M</b> <code>map()</code> <code>max()</code> <code>memoryview()</code> <code>min()</code>	<b>S</b> <code>set()</code> <code>setattr()</code> <code>slice()</code> <code>sorted()</code> <code>staticmethod()</code> <code>str()</code> <code>sum()</code> <code>super()</code>
<b>C</b> <code>callable()</code> <code>chr()</code> <code>classmethod()</code> <code>compile()</code> <code>complex()</code>	<b>G</b> <code>getattr()</code> <code>globals()</code>	<b>N</b> <code>next()</code>	<b>T</b> <code>tuple()</code> <code>type()</code>
<b>D</b> <code>delattr()</code> <code>dict()</code> <code>dir()</code> <code>divmod()</code>	<b>H</b> <code>hasattr()</code> <code>hash()</code> <code>help()</code> <code>hex()</code>	<b>O</b> <code>object()</code> <code>oct()</code> <code>open()</code> <code>ord()</code>	<b>V</b> <code>vars()</code>
	<b>I</b> <code>id()</code> <code>input()</code> <code>int()</code> <code>isinstance()</code> <code>issubclass()</code> <code>iter()</code>	<b>P</b> <code>pow()</code> <code>print()</code> <code>property()</code>	<b>Z</b> <code>zip()</code>
			<code>__import__()</code>

# Example Built-in functions:

`print()`, `len()`, `round()`, `input()`

---

Australian  
National  
University

- As a useful exercise, go to the [python.org](https://python.org) documentation for built-in functions and look up these up

```
[>>>
[>>> print('Some text here')
Some text here
[>>> len('Some text here')
14
[>>> round(1.1)
1
[>>> round(1.9)
2
[>>> input_string = input()
here is something I typed
[>>> print(input_string)
here is something I typed
>>>
```

# Imported Functions

Australian  
National  
University

- These work a lot like built-in functions, but need to be imported first and called with reference to the module they come from.

- Sometimes modules are referred to as packages or libraries

- A full list of Python modules is available at python.org:

<https://docs.python.org/3/py-modindex.html>

- Have a look at what is available – lots of useful stuff, eg:

math

random

zlib

json

statistics

pprint

pickle

getopt

csv

# Module functions example: math

- The functions available in modules would be rather annoying to have to write from scratch each time: `math.log10()`, `math.sin()`, etc
- To use a particular module, one must first import it:

```
>>> import math
```

- Then to use the functions, one must use **dot notation**:

```
>>> ratio = signal_power / noise_power
>>> decibels = 10 * math.log10(ratio)

>>> radians = 0.7
>>> height = math.sin(radians)
```

# How to find out more

Australian  
National  
University

<https://docs.python.org/3/library/math.html>

Python » English » 3.11.2 » 3.11.2 Documentation » The Python Standard Library » Numeric and Mathematical Modules » **math** — Mathematical functions

`docs.python.org`  
are your friend

This often the best way  
to find out how things  
work – the docs written  
by the developers.

If we scroll down this  
page far enough, the  
`math.sin()` is  
mentioned, as well as  
other useful things.

## Table of Contents

**math** — Mathematical functions

- Number-theoretic and representation functions
- Power and logarithmic functions
- Trigonometric functions
- Angular conversion
- Hyperbolic functions
- Special functions
- Constants

## Previous topic

**numbers** — Numeric abstract base classes

## Next topic

**cmath** — Mathematical functions for complex numbers

## This Page

[Report a Bug](#)  
[Show Source](#)

## **math.hypot**(\*coordinates)

Return the Euclidean norm, `sqrt(sum(x**2 for x in coordinates))`. This is the length of the vector from the origin to the point given by the coordinates.

For a two dimensional point `(x, y)`, this is equivalent to computing the hypotenuse of a right triangle using the Pythagorean theorem, `sqrt(x*x + y*y)`.

*Changed in version 3.8:* Added support for n-dimensional points. Formerly, only the two dimensional case was supported.

*Changed in version 3.10:* Improved the algorithm's accuracy so that the maximum error is under 1 ulp (unit in the last place). More typically, the result is almost always correctly rounded to within 1/2 ulp.

## **math.sin**(x)

Return the sine of x radians.

## **math.tan**(x)

Return the tangent of x radians.

## Angular conversion

### **math.degrees**(x)

Convert angle x from radians to degrees.

### **math.radians**(x)

Convert angle x from degrees to radians.

## Hyperbolic functions

**Hyperbolic functions** are analogs of trigonometric functions that are based on hyperbolas instead of circles.

### **math.acosh**(x)

Return the inverse hyperbolic cosine of x.

**math.asinh**(x)

# Exercises

---

Australian  
National  
University

- Complete Exercises 3-1, 3-2 and 3-3 of *Think Python*.

## Reading

- Chapter 3 of *Think Python* **AND/OR**
- Chapter 3 of *Automate the Boring Stuff with Python*

# Writing your own functions

---

Australian  
National  
University

- Why? If there are parts of your code that you use over and over in a single program, it makes good sense to turn these into a helper function:
  - Shorter code
  - Your code will be easier to read and understand
  - And – the best reason – you only need to change your code in one place when you modify it! It is annoying and very bug-prone to have to make the same changes in multiple different places in your code
  - Eventually, you will end up with a group of helper functions specific to your own work. And you will end up using these over-and-over.

# A simple, custom function

Australian  
National  
University

- Function definitions start with:
  - the `def` keyword
  - have a name followed by parentheses `()`
  - and a colon `:`
- First this is the definition line. It is followed by an indented code block that does the work of the function:

```
>>> def make_a_sound():  
...     print('quack')  
...  
>>> make_a_sound()  
quack
```

Lubanovic (2019) *Introducing Python*

- Functions are called by their name, with parentheses `()`
- A function must always be defined before it is called

# Function definition

Australian  
National  
University

```
def change_in_percent(old, new):  
    diff = new - old  
    return (diff / old) * 100
```

Diagram annotations: A bracket above the function name `change_in_percent` is labeled "name". A horizontal double-headed arrow below the first line of the function body, spanning the indentation, is labeled "4" and "spaces". A large curly brace to the right of the function body is labeled "block".

- A function definition consists of a name and a body (a block)
- The extent of the block is defined by indentation, which must be the same for all statements of a block
  - Standard indentation is 4 spaces
- This example has **parameters**
  - Parameters are specified in the function call, and are passed to the code block
- A custom function must be defined before it can be called

# Function parameters and return value

Australian  
National  
University

```
def change_in_percent(parameters old, new):  
    diff = new - old  
    return (diff / old) * 100
```

- Function (formal) parameters are (variable) names
  - These variables can be used only in the function body
- Parameter values will be set only when the function is called
- `return` is a statement
  - when executed, it causes the function call to end, and return the value of the expression

# A function call – with parameters

---

- To call a function, write its name followed by its (actual) **arguments** in parentheses:

```
>>> change_in_percent(489, 556)  
13.701431492842536
```

- The arguments are expressions
- Their number should match the parameters
  - Though there can be exceptions – more about this later
- A function call is an expression
  - The call in the example above is an expression that evaluates to the value `return'd` by the function

# Terminology: arguments and parameters

---

Australian  
National  
University

- **Arguments** are values that are passed to a function when it is called
- Say we make this function call:
  - `print("ATGTAATAG")`
  - `print()` is the function
  - `"ATGTAATAG"` is the string **argument** passed to `print()`
- **Parameters** are what arguments become when inside the code block within the function

# Functions can call other functions

Australian  
National  
University

- This is what real-world code is doing all the time. Most code you will write will use other functions to get things done

```
def ask_name():  
    print("Please enter your name: ")  
    name = input()  
    return name  
  
def calculate_length_of_string(the_string):  
    return len(the_string)  
  
def print_greeting(input_name):  
    name_length = calculate_length_of_string(input_name)  
    print("Hello, " + input_name + ". Your name is " + str(name_length) + " characters in length.")  
  
def interact():  
    interaction_name = ask_name()  
    print_greeting(interaction_name)  
  
interact()
```

The screenshot shows a terminal window titled "Console 1/A". It displays the execution of the Python script. The prompt "In [163]:" is followed by the command `runfile('/Users/dan/Desktop/untitled4.py', wdir='/Users/dan/Desktop')`. The output shows the program's execution: "Please enter your name:", the user input "Dan", and the final output "Hello, Dan. Your name is 3 characters in length." The prompt "In [164]:" is followed by a vertical bar, indicating the next input.

```
× Console 1/A  
  
In [163]: runfile('/Users/dan/Desktop/untitled4.py', wdir='/Users/dan/Desktop')  
Please enter your name:  
Dan  
Hello, Dan. Your name is 3 characters in length.  
  
In [164]: |
```

# Function definition order

Australian  
National  
University

- A function must be defined before it is first called.
- Not like:

```
interact() ←  
  
def ask_name():  
    print("Please enter your name: ")  
    name = input()  
    return name  
  
def calculate_length_of_string(the_string):  
    return len(the_string)  
  
def print_greeting(input_name):  
    name_length = calculate_length_of_string(input_name)  
    print("Hello, " + input_name + ". Your name is " + str(name_length) + " characters in length.")  
  
def interact():  
    interaction_name = ask_name()  
    print_greeting(interaction_name)
```

Moved function  
call to program  
beginning

```
Console 1/A  
  
In [164]: runfile('/Users/dan/Desktop/untitled4.py', wdir='/Users/dan/Desktop')  
Traceback (most recent call last):  
  
  File "/Users/dan/opt/anaconda3/lib/python3.9/site-packages/spyder_kernels/py3compat.py", line 356, in cc  
    exec(code, globals, locals)  
  
  File "/Users/dan/Desktop/untitled4.py", line 1, in <module>  
    interact()  
  
NameError: name 'interact' is not defined
```

# Order of evaluation

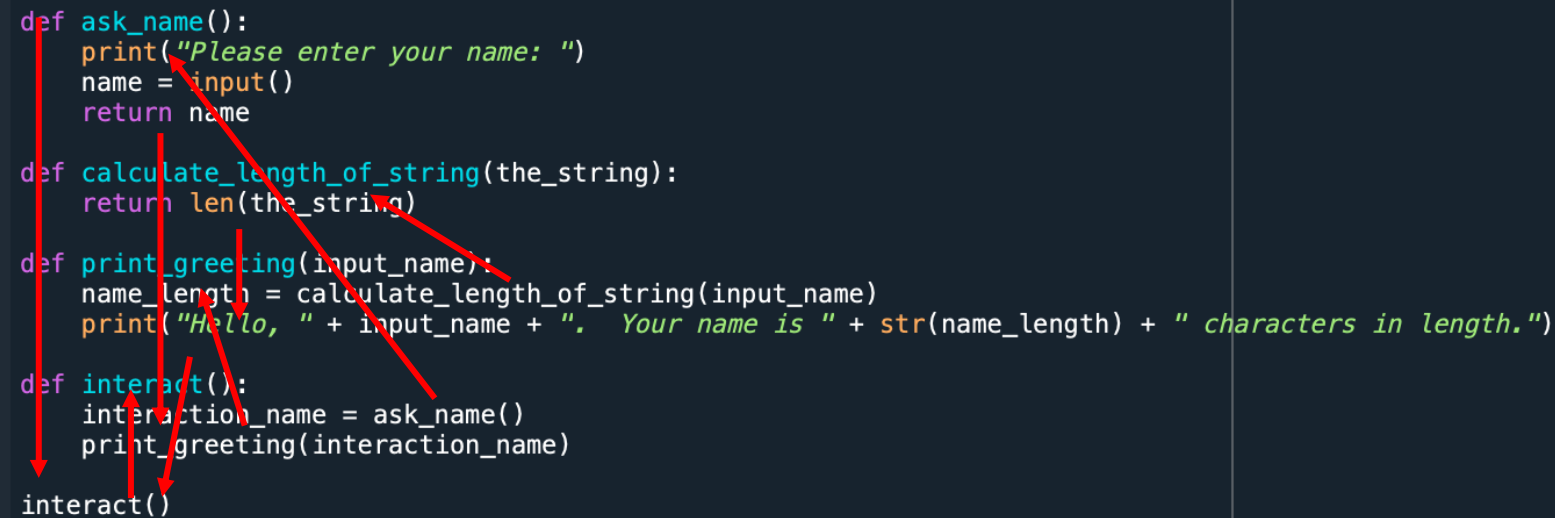

---

- The python interpreter always executes instructions one at a time in sequence; this includes expression evaluation
- To evaluate a function call, the interpreter:
  - First, evaluates the argument expressions one at a time, from left to right
  - Then, executes the function body with its parameters assigned the values returned by the arguments expressions
- Same with operators: first arguments (left to right), then the operation

# Flow of execution

- Calling a function will interrupt the processive flow of program execution
- Calling a function causes the execution to skip to that function and continue executing from that position

```
def ask_name():  
    print("Please enter your name: ")  
    name = input()  
    return name  
  
def calculate_length_of_string(the_string):  
    return len(the_string)  
  
def print_greeting(input_name):  
    name_length = calculate_length_of_string(input_name)  
    print("Hello, " + input_name + ". Your name is " + str(name_length) + " characters in length.")  
  
def interact():  
    interaction_name = ask_name()  
    print_greeting(interaction_name)  
  
interact()
```

- Execution continues until the end of the function is reached (and it returns to executing where the call was originally made)

# Concept: the call stack

Australian  
National  
University

- The 'to-do list' of where to come back to after each current function call is called the (execution or call) stack
  - When evaluation of a function call begins, the current instruction sequence is put 'on hold' while the expression is evaluated – and the function calls begin to 'stack up'
- ```
def ask_name():  
    print("Please enter your name: ")  
    name = input()
```

- Graphically:

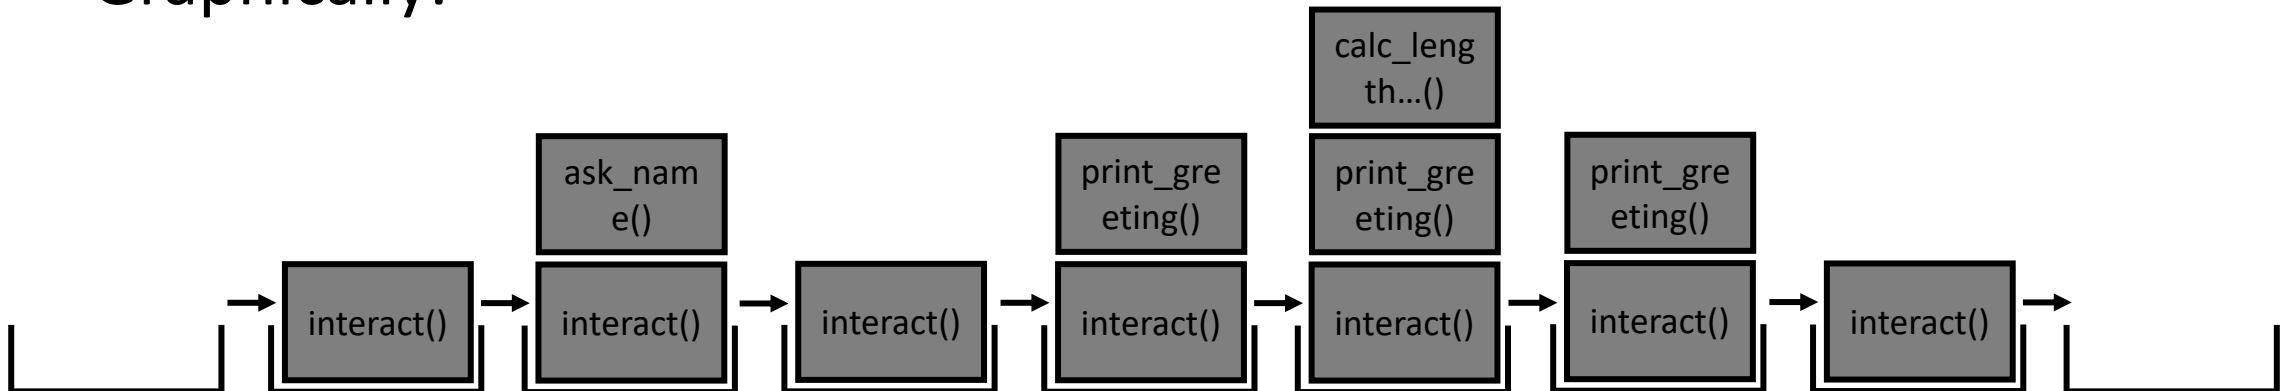

```
def ask_name():
    print("Please enter your name: ")
    name = input()
    return name

def calculate_length_of_string(the_string):
    return len(the_string)

def print_greeting(input_name):
    name_length = calculate_length_of_string(input_name)
    print("Hello, " + input_name + ". Your name is " + str(name_length) + " characters in length.")

def interact():
    interaction_name = ask_name()
    print_greeting(interaction_name)

interact()
```

# Scope - Sweigart, *Automate the Boring Stuff with Python*, Ch 3

Australian  
National  
University

- We haven't talked yet about scope – this is important
- So far, we have assumed that all defined variables are accessible all the time – this is known as **global** scope
- But global scope becomes hazardous as:
  - A program gets larger
  - Includes code that comes from other developers (you might both use the same variable name)
- The parameter variables within a single function are **local** to the code block. If you try to access one of these outside the function code block, you will get an error.

# Graphically:

Australian  
National  
University

scope.py

```
def print_gene():  
    gene_name = 'p53'  
    print('In print_gene: ' + gene_name)  
  
def print_protein():  
    protein_id = 'TP53'  
    gene_name = 'Unknown'  
    print('In print_protein: ' + protein_id + ' ' + gene_name)  
  
gene_name = 'BRCA2'  
print_gene()  
print('In main: ' + gene_name)  
print_protein()
```

Output:

```
In print_gene: p53  
In main: BRCA2  
In print_protein: TP53 Unknown
```

## Program: scope.py

### Global

```
gene_name = 'BRCA2'
```

### Function: print\_gene()

#### Local

```
gene_name = 'p53'
```

### Function: print\_protein()

#### Local

```
protein_id = 'TP53'  
gene_name = 'Unknown'
```

# Within a function, parameters are local

---

Australian  
National  
University

- Variables created/assigned in a function (including parameters) are **local** to that function:
  - Local variables have scope limited to the enclosing block
  - The interpreter uses a new namespace for each function call
  - Local variables that are not parameters are undefined before the first assignment in the function body. Then remain local to the function block
  - Variables with the same name used outside the function are unchanged after the call
- Within a function, you can still access variables in the **global** scope
- But, within function **local** scope, you *cannot* access the **local** scopes of other functions

# Why make it complicated?

---

- There are very good reasons why every section of code should not be able to access the variables controlled by other sections.
  - For one thing, as your program gets bigger, the **namespace** of the program will start to get crowded.
  - You might be using the same variable name for two different things.
  - If you are using code from other developers (like importing functions), they might be using the same variable names as your program – but for different things
  - It makes good sense to compartmentalise variable scope, to avoid *namespace-collisions*

# The call stack

# None values

Australian  
National  
University

- Some variables contain nothing. Not zero. `None` means null, nothing, undefined.
- `None` type:

```
>>> print(type(None))  
<class 'NoneType'>
```

Downey (2015) Think Python, 2<sup>nd</sup> Ed., Ch 3

- Not the same as zero:

```
>>>  
>>> none_var = None  
>>>  
>>> none_var == 0  
False  
>>>
```

- A void value. Just not defined. Some other languages have `NULL` values.
- Why are `NoneType` values useful?

# Functions withOUT `return` values

---

Australian  
National  
University

- One place you might encounter `None` is when a function has no `return` statement
- If execution of a function reaches the end of the body without encountering a `return` statement, the function call returns `None`
- *Note:* with `iPython`, or interactive mode with `Spyder`, the interpreter does not print the return value of an expression when the value is `None`.

# The function docstring

Australian  
National  
University

- It is good practice to document your function with a *docstring*
- As simple as a sentence bound with ' ' '

```
def change_in_percent(old, new):  
    '''Return change from old to new, as a percentage of the old value.  
    Old value must be non-zero.'''  
    return ((new - old) / old) * 100
```

- A docstring is a string literal written as the first statement inside a function's body
- Acts like a comment, but accessible through the built-in help system
- Describe *what* the function does (if not obvious from its name) – and its *limits* and *assumptions*

# Exercises
